Title: Genetic diversity study in Napier grass (*Cenchrus purpureus*) collections and progenies

By: Tadelech Bizuneh

Year: 2020, Addis Ababa University

Abstract

Application of currently available advanced molecular tools and characterization of Napier grass forage crop is limited. Furthermore, ILRI genebank held collection of this forage grass from different part of the world, but with little information on the genetic diversity of the collection. Therefore, the objective of this study was to evaluate the extent of the genetic diversity of Napier grass accessions collected from different parts of the world and progeny plants raised from naturally produced seeds. The genomic DNA was extracted from leaves of 347 Napier grass genotypes and genotyped by the DArTseq platform. A total of 96,454 Silico DArT and 96,321 SNP markers were generated, of which highly informative 1001 SNP markers were selected for diversity analysis after screening. The average polymorphic information content (PIC) values of Silico DArT and SNP markers were 0.21 and 0.15 and average heterozygosity of 0.26 and 0.18 respectively. Two major groups and ten sub-clusters were identified by population stratification and diversity analysis using STRUCTURE and hierarchal clustering. Discriminant analysis of principal component (DAPC) further confirmed the sub-clusters. Analysis of molecular variance (AMOVA) showed significant (P<0.00) variation among the populations. The mean values of fixation index (Fst) per cluster ranged from 0.34 in cluster VI, that consisted of progeny plants, to 0.76 in cluster VII, that consisted mostly of the ILRI collections, and the largest divergence (0.38) was also between sub-cluster IV and VII. All these parameters showed the presence of high diversity and genetic differentiation among the assayed Napier grass genotypes.

Key words: *Cenchrus purpureus*, DArTseq markers, Genetic diversity, Napier grass, progeny plants

Contents

1 Introduction

Napier grass (*Cenchrus purpureus (*Schumach) *Morrone syn. Pennisetum purpureum Schumach.)* or elephant grass is a monocot perennial grass that belongs to the family Poaceae (grass family) and genus *Cenchrus*. The genus *Cenchrus* is very diverse, consisting of a heterogeneous group of species with different basic chromosome number and ploidy level. Among these species Napier grass is an allotetraploid species with a basic chromosome number of 7 (2n =4x=28) (Singh and Obeng, 2013). Napier grass is widely cultivated as a forage crop in the tropical and subtropical regions of the world. It is mainly used as animal feed due to its ease of establishment and management, high palatability and high dry matter production that can provide up to 78 tons of dry matter/ ha/ year (Negawo *et al.,* 2017; Oliveira *et al.,* 2017; Maria *et al.,* 2014). In addition, Napier grass has the potential to produce biofuels such as alcohol, ethanol and butanol, and methane since it has high cellulose content that can be used as carbon (energy) source (Romero *et al.,* 2019; Roslan *et al.*, 2020; Yasuda *et al.,* 2013). It is also, considered as one of the exceptional potential phytoremediator plants to tackle heavy metal and chemical environmental pollutions due to its rapid growth rate, ease of establishment, low cost of management system and high level of biomass that can withstand and enable it to accumulate large amounts of pollutants (contaminants) in their system; ability to grow on different environmental situations even on poor soil conditions (Lotfy and Mostafa, 2014; Roslan *et al.,* 2020; Tananonchai and Sampanpanish, 2018). According to Yang *et al.* (2020) through the use of liquid extraction method that directly remove heavy metals from plants; the content of heavy metal in Napier grass was lowered (detoxified) while the crude protein was retained to be used safely as animal feed or energy production materials. Moreover, some Napier grass cultivars were identified as potential plants in the "push-pull insect management strategy" and used to trap African stem borer, *Busseola fusca* Fuller (Lepidoptera: Noctuidae), an insect that causes production loss in maize and sorghum (Khan *et al.,* 2007).

The international livestock research institute (ILRI) forage genebank holds more than 130 Napier grass accessions collected from different parts of the world. These collections consist from different sources where 60 accessions are ILRI's 'in trust' collection which represents a diverse set of genotypes assembled from a range of environments and origins, of which eight accessions are hybrids of *C. purpureus × C. americanus* crosses, and the remaining 62 accessions were introduced to ILRI from different institutions, including the Brazilian Agricultural Research Corporation (EMBRAPA), the Crop Genetics and Breeding Research Unit, USDA–ARS, Tifton, Georgia and the International Crop

Research Institute for the Semi-Arid Tropics (ICRISAT), India. These collections are maintained in-situ at the Bishoftu and Ziway (Batu) sites in Ethiopia (Negawo *et al*., 2017). The collection is characterized by a high amount of genetic diversity and is highly variable in terms of agronomic and morphological characters (Muktar *et al.,* 2019). Though the collections represent diverse sets of genotypes that are variable in genetic and phenotypic traits, still the diversity and population size is very limiting in selecting different traits for East Africa's different agroecological zones. Furthermore, the study by Muktar *et al.* (2019) indicated the presence of long haplotype blocks and less linkage disequilibrium (LD) decay in the ILRI in trust collections which were maintained via vegetative propagation than the EMBRAPA materials, that had passed through an active breeding program, suggesting breeding the ILRI collection and developing progeny population would increase the available genetic variability. Thus, developing a breeding population would be utilized for molecular genetic studies such as quantitative trait loci (QTL) mapping and genetic diversity analysis. Introducing new materials from international institutes would be good and the easiest way to increase the diversity, even though the use of the introduced materials may be restricted by research compliances and copy rights. The other way to increase the diversity is by crossing the most genetically distant genotypes and analysing the progenies to identify unique genotypes.

The application of currently available advanced molecular tools and characterization of this forage crop is limited. Utilization of molecular technologies is essential to assess and identify the variability found in this forage crop accurately in a short time and can support improvement and conservation efforts. But so far, a handful of publications that are based on the use of low density molecular markers mostly for diversity analysis (Azevedo *et al.*, 2012; Paudel *et al.,* 2018; Wanjala *et al.,* 2013) and a couple of publications that are based on the advanced sequencing technologies (Muktar *et al.,* 2019; Zhou *et al.,* 2018), have been produced on Napier grass genotyping. Zhou *et al.* (2018) used Illumina-based sequencing technology to develop about 50 EST-SSR markers and 6 SNP markers through transcriptome analysis that were used to facilitate the genetic diversity study in Napier grass. A recent report (Muktar *et al.,* 2019) used the GBS method of the DArTseq platform for the development of genome-wide sequence-based molecular markers (dominant (SilicoDArT) and co-dominant (SNP) markers) for 105 Napier grass accessions.

The current study evaluated the level and patterns of genetic diversity in Napier grass accessions and progeny plants maintained in the ILRI forage gene-bank using genome-wide markers from the DArT-seq platform to generate baseline information for breeding, conservation and its future utilization.

1.2. Objectives of the study

General objective

To evaluate the level and patterns of genetic diversity in Napier grass accessions and progeny plants maintained in the ILRI forage gene-bank using genome-wide markers from the DArT-seq platform to generate baseline information for breeding, conservation and its wise use.

Specific objectives

- To assess genetic variation among and within accessions of Napier grass (*Cenchrus purpureus*) collections and progeny plants.
- To identify potential genotypes that could be used in the future Napier grass breeding program
- To identify potential duplicate and unique genotypes

2 Literature review

2.1 Origin and distribution of Napier grass

Napier grass (*Cenchrus purpureus* (Schumach.) Morrone syn. *Pennisetum purpureum* Schumach.), commonly called elephant grass originated from the tropical region of sub-Saharan Africa (Clayton *et al.,* 2013) and has been distributed as a forage crop into most tropical and subtropical regions all over the world (Negawo *et al*., 2017). It was introduced into the USA in 1913 (Burton, 1990), into Brazil from Cuba in around 1920 (Daher *et al.,* 2002), into Central and South America and the West Indies in the 1950s and into Australia in the 1960s. Currently, it is naturalized to these areas and sometimes becomes invasive (CABI, 2014). It is often considered as a weed in crops, growing along roadsides, waterways, wetlands, floodplains, swamps, forest edges, disturbed areas and wastelands (Francis, 2004). Since it withstands drought, it is a pioneer species in arid lands such as the Galapagos Islands (CABI, 2014).

2.2 Taxonomy and botanical descriptions of Napier grass

2.2.1 Taxonomy

Elephant grass or Napier grass (*C. purpureus*), originally described and classified as *Pennisetum purpureum* Schumach (Stapf and Hubbard, 1934) and the taxon *Cenchrus purpureus* (Schumach.) Morrone was proposed in 2010 as a replacement for *Pennisetum purpureum* Schumach (Chemisquy *et al.,* 2010).

Cenchrus is the richest genus that consists about 140 species, including important cultivated species such as Napier grass, Pearl millet and Kikuyu grass (Kikuyu and Mithen, 1987). The species belonging to this genus constitute a heterogeneous assemblage with different basic chromosome numbers of 5, 7, 8 and 9, varying ploidy levels from diploid to octoploid with sexual or apomictic reproductive behavior and annual, biennial or perennial life cycles (Negawo *et al.,* 2017).

2.2.2 Botanical descriptions and ecology of Napier grass

Elephant grass (*C. purpureum)* is a perennial and one of the highest yielding monocot C4 major tropical grasses. It is a very versatile species that can be grown under a wide range of ecological conditions and systems: dry or wet conditions, smallholder or large-scale agriculture. It is a valuable forage and very popular throughout the tropics, as cut-and-carry animal feed (Negawo *et al.*, 2017).

Napier grass is a summer-growing grass that grows from sea level up to an altitude of 2500 m. It is more productive in places where temperatures range from 25 °C to 40 °C, annual rainfall is over 1500 mm and on rich, deep soils, such as friable loams (FAO, 2015; Skerman and Riveros 1990). It is not able to grow below 15 °C and is sensitive to frost, though it can regrow from the stolons if the soil is not frozen (Duke, 1983). It has some level of tolerance to drought and can grow in areas where the rainfall range is 200-4000 mm (Singh *et al.,* 2013), but it undergoes some morphological changes including leaf rolling, reduced stomatal conductance and enhanced water use efficiency to withstand water stress conditions (Negawo *et al.,* 2017). On the other hand, this grass doesn't tolerate flooding; it prefers well-drained soils. When there is a poor drainage system, it is best to grow it on raised beds (Göhl, 1982). However, it is able to grow on poorly drained clays, with a fairly heavy texture, or excessively drained sandy soils with a pH ranging from 4.5 to 8.2 (FAO, 2015). Elephant grass is a perennial full day sunlight species that can still grow under partial shade but does not withstand complete shade under a dense tree canopy (Francis, 2004).

Morphologically it is described as a robust, tall, perennial grass with a vigorous root system that penetrates deep into the soil, developing from the nodes of its rhizomes; and it forms dense thick clumps, up to 1 m across. The culms are coarse, perennial, and up to 4-7 m in height, branched overhead. The leaves are flat, linear, and hairy at the base and up to 100-120 cm in length and 1-5 cm width, with a bluish-green color (some genotypes have purple coloured leaves), leaf margin is finely toothed and leaf blade has a prominent midrib (Singh *et al.,* 2013). The inflorescence is a stiff terminal bristly spike, up to 15-20 cm in length, yellow-brown to purplish in color. The spikelets are 4-6 mm long, surrounded by 2 cm long plumose bristles and arranged around a hairy axis that falls at maturity. There is little or no seed formation due to the grass's self-incompatibility and exogamous nature. When seeds are present, they are very small (3,000,000 seed/kg) (Francis, 2004; Mannetje, 1992).

2.3 Mode of propagation

2.3.1 Sexual propagation of Napier grass

The sexual propagation of Napier grass is limited due to their vegetative propagation nature, however some extent of sexual propagation through cross pollination have been reported (Negawo *et al*., 2017). The sexual propagation through cross pollination often results in seeds of a mixed lot, thus the plants produced from them are not uniform and their performance is also unpredictable. In addition, the seeds germinate poorly, and seedlings are weak even when they grow fully, poor seed-setting and shattering make seed availability a problem. Still, some of the ILRI Napier grass accessions growing in the Bishoftu and Ziway sites produce seeds, which need further investigation whether the seeds have been produced through apomixis or sexual reproduction. A preliminary genetic diversity analysis among progeny plants raised from seeds suggested that sexual reproduction by cross pollination is possibly the major mechanism for the seeds production. In addition, Napier grass is naturally cross-compatible with pearl millet (*Cenchrus americanus*, 2n = 2x = 14) and their crosses result in the production of triploid hybrids, which are sterile and can be propagated vegetatively by means of stem cuttings (Negawo *et al*., 2017).

According to Souza *et al*. (2019), about 95% of Napier grass seeds are predominantly derived from cross-fertilization and the outcrossing rate in their study reveals it is an allogamous grass with multilocus (tm) and unilocus outcrossing rates (ts) of 0.953 and 0.895, respectively. Their result is also consistent with the previous reports by Azevedo *et al. (*2012); Harris *et al.* (2010) which described

Napier grass as an allogamous species with high heterozygosity since outcrossing guarantees genetic variability, and thus creates new combinations of alleles within a species.

Napier grass, being a strictly out crosser (95%), is mostly self-incompatible and plants produced by self-fertilized (which is very rare) produce few viable seeds and the seeds show low germination index and the resulting plants have low vigour (Pereira *et al*., 2010; Souza *et al*., 2019; Hanna *et al.,* 2004). Self-incompatibility varies greatly among accessions and is directly affected by environmental factors such as temperature, humidity, different environments and artificial pollinating techniques (Souza *et al*., 2019).

In addition, protogyny, which affects the production of sexual seeds, has already been described in this species. According to Pereira *et al*. (2010), stigmas are receptive between 3 to 5 days prior to the pollen grains release which makes fertilization within the same inflorescence unfeasible. Difficulties in self-fertilization limit the development of hybrids which offer opportunities for greater uniformity, higher selection intensities, absolute parental control and maximum exploitation of heterosis in Napier grass (Canto *et al.,* 2016).

2.3.2 Asexual propagation of Napier grass

Asexual or vegetative propagation of Napier grass is the most common method of propagation. Asexual propagation of Napier grass through stem chopping consists of at least 3 nodes in which two of these nodes are buried in the soil. The planting row width ranges from 50 to 200 cm and distance within rows ranges from 50 to 100 cm (Mannetje, 1992). After planting, elephant grass grows vigorously and can be up to 4 m high in three months (Skerman *et al.,* 1990). It is fast-growing and has a high annual productivity that depends on the climate, especially temperature and rainfall (Aroeira *et al.,* 1999; Artus-Poliakoff *et al.,* 1991). Elephant grass requires high levels of fertilizer and regular water supply (Mannetje, 1992) and the yields range from 20 to 80 t DM/ha/year under high fertilizer inputs (Francis, 2004; Skerman *et al.,* 1990), while 2-10 t DM/ha/year when there is no, or inadequate, fertilizer input (Bogdan, 1977). Cuttings can be made at 45-90-day intervals, depending on location (FAO, 2015).

2.4 Economic value of Napier grass

Napier grass has a lot of economic importance, it is primarily used as a fodder crop for small scale farmers since it grows with little nutrient supply and ease of management. The perennial nature of the grass and year-round availability makes it the first choice as a forage crop. It is also used as an

alternative bioenergy source, as a phytoremediation plant and as pest management in the push - pull management system (Negawo *et al.*, 2017).

A number of traits, including high dry matter production, ease of establishment and regeneration, persistence, and enhanced water use efficiency make Napier grass the primary forage of choice by small-scale dairy farmers (Nymbati *et al.,* 2010). Napier grass follows C4 photosynthetic pathway and is considered to have a competitive advantage over C3 grass species when grown in tropical and sub-tropical regions (Taylor *et al.,* 2011). It also has the capacity to reduce shoot dry matter and maximize carbon assimilation during times of water stress, making it a desirable forage crop in areas prone to droughts (Cardoso *et al.,* 2015). It is often fed fresh in cut and carry systems. It can also be chopped into pieces prior to feeding to reduce coarseness of leaves and stems for the animal. Moreover, wilting after chopping in the sun for several hours reduces moisture, facilitates rumination, stimulates appetite and thus improves forage utilization (Moran, 2011).

Napier grass (*C. purpureus)* genotypes were also evaluated by (de Morais *et al.*, 2009) for bioenergy production and they indicated that genotypes such as Cameroon, CNPGL F 06-3 and Bag 02 were promising for bioenergy production purposes. Other studies in Brazil's semiarid area using gypsum by (dos Santos *et al.,* 2015) also state that elephant grass, mainly Cameroon and Gramafante varieties, is a great potential energy crop. According to (Favare *et al.*, 2019), Elephant grass is an excellent alternative for bioenergy production mainly, due to its high percentage of stem and dry matter yield.

On other hand, eight Napier grass varieties were evaluated for their potential role as trap plants in the management of the African stemborer, *Busseola fusca* Füller (Lepidoptera: Noctuidae) in a push–pull strategy (Khan *et al.,* 2007). They concluded that the Napier grass cultivar called Bana had potential for use as a trap plant in the management of *B. fusca* in a 'push–pull' strategy, but the effectiveness of such a strategy would strictly depend on proper establishment and management of these companion plants.

In addition, Napier grass is also considered as one of the exceptional phytoremediator plants to tackle environmental pollutions due to its fast growth rate, high level of biomass yield, ease of establishment, low management cost and tolerance to pollutions; that enable it to accumulate large amount of pollutants (contaminants) in their system and able to degrade it (Lotfy and Mostafa, 2014; Roslan *et al.,* 2020; Tananonchai and Sampanpanish, 2018).

2.4.1   Napier grass cultivation and its limitations

Napier grass as a major fodder for a dairy farm in East and central Africa, grown by more than 70 percent of smallholder dairy farmers in Kenya (Mulaa *et al.,* 2013); Uganda (Kabirizi *et al.,* 2007) and Tanzania (Pallangayo *et al.,* 2008). It constitutes between 40 to 80% of the forage for small holder dairy farmers (Staal *et al.,* 1997). In general, ease of establishment, management and regeneration, and its enhanced water-use efficiency make it primary forage of choice in the regions of tropics and subtropics for smallholder dairy farmers (Negawo *et al.,* 2017) however, the production of this forage crop is currently facing challenges from abiotic and biotic conditions such as climate change, Napier grass stunt and head smut diseases, respectively caused by a phytoplasma and a fungus *Ustilago kameruniensis*, which spread by wind, farm tools, infected plants, water, and animal manure respectively, have caused forage yield reduction of up to 90% (Mulaa *et al.,* 2013), and these biotic factors are currently the biggest threats to forage production and hence dairy sector in the East and Central Africa region.

Thus, information on the range of diversity of the available genetic resources of this important forage crop will help in the development of varieties that can overcome this production and productivity constraints.

2.5   Genetic diversity study of Napier grass

Precise assessment of the level of genetic diversity can be invaluable in plant breeding for diverse applications including: analysis of genetic variability in cultivars, identifying diverse parental combinations to create progenies with maximum genetic variability for further selection, and introgression of desirable genes from diverse germplasm into the available genetic base (Mohammadi and Prasanna, 2003). Therefore, a major focus of research in molecular genetics has been to determine the amount of genetic variation in populations and describe the possible mechanisms of maintaining such variability in meeting new environmental challenges (Weir, 1996).

Specifically, diversity information that can be derived from molecular analyses of Napier grass germplasm will help to determine the degree of relationships of the different germplasm within and among breeding populations and the germplasm held at the ILRI genebank, used in future association study to identify outstanding morphological and agronomic characters present in the germplasm. I will also provide the basic data for the effective utilization of the germplasm in the grass breeding programs for its improvement and conservation.

2.6 Genetic markers and their applications for genetic diversity analysis in Napier grass

Analysis of genetic diversity within and among populations involves the use of different genetic markers. Now, genetic markers are used in both basic plant research and plant breeding programs to characterize plant germplasm for gene isolation, marker-assisted introgression of favourable alleles, to produce improved varieties (Henry, 2001), and to obtain information about the genetic variation of populations for conservation and management purposes. There are three main classes of genetic markers for genetic diversity analysis: morphological markers, biochemical or protein markers, and DNA based molecular markers.

2.6.1 Morphological markers

Qualitative traits are usually controlled by a single locus and their expression is the same over a range of environmental conditions. These traits can be used as markers as they are usually visually described. These traits include seed shape, flower color, and seed colour (Bagali *et al.,* 2010). The advantage of using this marker for genetic diversity analysis within and among the population is that it does not require any sophisticated equipment and it is the most direct method. However, they are limited in number and subject to changes in environmental factors and may vary at different developmental stages (Mondini *et al.,* 2009). In Napier grass morphological markers were used by Van De Wouw *et al.* (1999) to assess variation among 53 accessions and these researchers indicated that some accessions could not be distinguished from each other by any of the characters observed. In general, morphological markers are not as such a reliable method to measure genetic differences related to productivity since most of the yield related traits are quantitate traits that are controlled by multi-loci and gene expression is influenced by different factors, including environmental factors.

2.6.2 Biochemical or protein based molecular markers

To overcome the limitation of morphological markers, protein-based biochemical markers and DNA based markers have been developed (De Vicente and Fulton, 2003). Biochemical marker-based analysis of genetic diversity is the separation of proteins into specific banding patterns. It is a fast method that requires only small amounts of isozymes or protein. Napier grass polymorphism based on isozymes and total proteins (TP) was assessed by Bhandari *et al*. (2006) and could distinguish variations among the assessed accessions. Since only a limited number of enzymes are available and

not evenly distributed throughout the genome of the organism, they do not clearly show diversity at the genome level (Mondini *et al.,* 2009).

2.6.3 DNA based molecular markers

Molecular markers use naturally occurring polymorphisms in DNA sequences due to mutation, recombination, or in some cases due to errors during DNA replication (Gupta *et al*., 1999). Molecular markers are highly polymorphic and heritable, relatively simple to detect, distributed throughout the genome and completely independent of environmental conditions. They enable the detection of genetic variability at any stage of plant development. Main disadvantage of this technique is it requires more complex equipment and procedures. DNA based molecular markers are classified into two as hybridization-based marker and PCR based markers.

2.6.3.1 Restriction Fragment Length Polymorphism (RFLP)

Restriction Fragment Length Polymorphism (RFLP) is the first DNA based molecular marker that works by hybridization and has been an important tool for plant genome mapping (Jiang, 2013). It involves the digestion of genomic DNA into fragments with specific restriction enzymes and utilizes the variation in fragment length to assess differences. Variations in fragment length arise due to change (mutation) at an enzyme recognition site, single base pair substitution, insertion of genetic materials, such as transposable element, or by tandem duplications, deletions, translocations, or other rearrangements (Gupta *et al.,* 2002).

Smith *et al.* (1993) used RFLP and RAPD to study genetic diversity of Napier grass. RFLP is co-dominant locus-specific marker and is highly reproducible which can be used for different related organisms since they allow synteny (conserved order of genes between related organisms). The main shortcoming of RFLP markers is its tedious and time-consuming procedures.

2.6.3.2 PCR based markers

I.   Random Amplified Polymorphic DNA (RAPD)

RAPD marker usually uses 10 nucleotides long single arbitrary primer to amplify the genomic DNA of different amplicon sizes. The difference in fragment length is due to some changes in the sequences found in primer annealing sites and between the two priming sites (Williams *et al.,* 1990). As stated by (Negawo *et al.,* 2017), Smith and co-workers were the first to use RAPD and AFLP markers to analyze diversity in Napier grass and able to clearly distinguish Napier grass accessions from its hybrid and

pearl millet. The main limitation of RAPD marker is low reproducibility and its dominant nature (Williams *et al.,* 1990).

I. Amplified Fragment Length Polymorphism (AFLP)

AFLP marker was originally developed for universal DNA fingerprinting analysis (Vos *et al.,* 1995). It is robust and relatively insensitive to PCR reaction conditions and highly reproducible. AFLP is used for the rapid screening of genetic diversity and intraspecific variation (Russell *et al,* 1997). Wanjala *et al.* (2013) used AFLP to study genetic diversity of Napier grass collections from east African region maintained by the ILRI forage genebank and they were able to discriminate and group the collections efficiently. The limitations of AFLP include difficulties in interpretation of band profiles in terms of loci, allele, and dominance.

II. Simple Sequence Repeat (SSR)

Simple sequence repeat (SSR) markers also called microsatellite markers are very short DNA (mono, di-, tri-, tetra-, penta-, and hexanucleotide) motifs usually characterized by a high degree of repetition even in thousands. They are evenly distributed throughout the genome of the organism (Singh *et al.,* 2010) and their polymorphism reflects differences in simple repetitive sequences of defined regions of the genome. Products of different sizes or lengths can be amplified with a pair of primers flanking different microsatellite regions. Typically, only a single locus is amplified resulting in single or double bands depending on the homozygosity or heterozygosity of that specific locus (Singh *et al.,* 2010). In general, SSR markers are locus-specific and co-dominant, simple to operate, abundant throughout the genome and highly reproducible. It has high rates of transferability from species to species. The cross-amplification rate of microsatellite markers between species of the same genus can vary from 50 to 100% (Azevedo *et al.,* 2012).

This transferability property of SSR markers was assessed between pearl millet (*C. americanus* syn. *Pennisetum glaucum*) and Napier grass (*C. purpureus* syn. *Pennisetum purpureum*) by Azevedo *et al.* (2012) to evaluate the genetic diversity and phylogenetic relationships among Napier grass accessions by using SSR markers that were originally developed for pearl millet. According to their study, about 55.5% of the primers showed successful cross-amplification to study the diversity of Napier grass and enabled them to cluster 107 accessions into three main groups. Kandel *et al.* (2016) also studied the genetic diversity of Napier grass using microsatellite, Single-Nucleotide Polymorphism (SNP) and Insertion-Deletion markers, which were originally developed for pearl millet. Those studies showed

the possibility of cross-amplification of the markers within the genus. The main limitation of this marker is the requirement for prior sequence information for the primer flanking regions to develop a pair of primers.

III.   Inter Simple Sequence Repeat (ISSR)

Inter Simple Sequence Repeat (ISSR) marker was introduced in 1994 to asses genetic variation below the species level; mainly for studying population structure and differentiation of cultivated plants (Gupta *et al.,* 1994).This marker technique involves the amplification of DNA segment present in between two identical microsatellite repeat regions oriented in opposite direction (Joshi *et al.,* 2000). In Napier grass, Babu *et al.* (2009) used ISSR, together with RAPD, markers in the analysis of genetic diversity among thirty Napier grass genotypes from a wide geographical distribution.

IV.   Single-Nucleotide Polymorphism (SNP)

SNP (Single Nucleotide Polymorphism) markers occur at high frequencies and are distributed across the genome. SNP marker differences in DNA sequence among genotypes are identified through an expensive and laborious DNA sequencing process. At first, SNPs revolutionize biomedicine, but since the technology depends on intensive genomic sequencing and a high cost of analysis that cannot be covered in agriculture or basic research. However, the development of a solid-state, open-platform method for DNA polymorphism analysis, for example the application of genotyping-by-sequencing (GBS) method, offers a low-cost high-throughput, robust system with minimal DNA sample requirement and is capable and has been providing high quality genome-wide coverage information even in organisms without any DNA sequence information such as Napier grass (Muktar *et al.,* 2019).

2.6.4 DArTseq markers

The DArTseq technology is one of the GBS methods, it uses a combination of genome complexity reduction using restriction enzymes and next generation sequencing (NGS) and produces high-density genome-wide dominant (SilicoDArT) and co-dominant (SNP) markers. This technology is an excellent approach and has been developed for the whole-genome profiling of Napier grass breeding programs and genetic resources conservation at the ILRI forage gene bank (Muktar *et al.,* 2019).

2.7 Parameters for genetic diversity analysis

Genetic diversity can be measured using different statistical methods. It can be in terms of the Coefficient of Correlation, genetic distance, and heterozygosity.

Coefficient of Correlation is defined as the probability that alleles of two individuals are identical by descent or by state. The value of coefficient of correlation ranges from zero, when the genotypes are completely unrelated; to one, when the two individuals have many alleles in common or are almost identical (Martin *et al.,* 1991). This Coefficient of Correlation is used to cluster genotypes into similar groups (Bered *et al.,* 2002). Coefficient of correlation (rxy) can be computed for all pairwise combinations of genotypes from pedigree information using the formula given by Falconer and Mackay (1996):

$$r\text{xy} = 2\text{f xy}|\sqrt{(1 + Fx)(1 + Fy)}$$

Where fxy= a coefficient of co-ancestry, Fx and Fy = inbreeding coefficients of X and Y, respectively.

Genetic distance is used to measure the genetic divergence between species or populations within a species, whether the distance measures degree of differentiation or time of divergence from a common ancestor. Many types of estimation of genetic distance are available and the appropriate choice of a genetic distance measure, on the basis of the type of the variable and the scale of measurement, is an important component in analysis of genetic diversity among genotypes. For the first time Nei defined genetic distance as the difference between two entities that is explained by allelic variation (Nei, 1972). Later on, it was defined in a more comprehensive way by Beumont *et al.* (1998) as any quantitative measure of genetic difference at either sequence or allele frequency level calculated between individual genotypes or populations. Currently there are different methods that are used to measure genetic diversity from molecular data. Some of them include Euclidean distance, Roger's distance, Fixation index (Fst) and analysis of molecular variance (AMOVA). Allelic diversity is used when genetic marker data or molecular marker data are interpreted in terms of locus/allele model. This allelic diversity may be expressed as the: a) percentage of polymorphic loci (p); b) mean number of alleles per locus (n), and; c) total gene diversity or expected heterozygosity (He), and polymorphic information content (PIC) (Bhanu, 2017). Percentage of polymorphic loci (p) gives an estimate of number of polymorphic loci with respect to total loci including polymorphic and monomorphic loci and is calculated as:

$$p = \frac{Np}{Nt} * 100$$

N_p is the number of polymorphic loci and N_t is the number of total loci

Heterozygosity (He) and polymorphic information content (PIC), which is an indirect estimate of the number of alleles per locus, can be calculated as:

$He = 1 - \sum_{i=1}^{n}(Pi)^2$ and $PIC = 1 - \Sigma\ p_i^2 - \Sigma\ \Sigma\ p_i^2 p_j^2$

Where, P_i and p_j are the frequency of ith and j^{th} allele at a particular locus

The PIC is a good index for genetic diversity evaluation and used to evaluate the level of gene variation, with values ranging from zero to one. A PIC value > 0.5, indicates a locus with high diversity, a PIC value <0.25 a locus with low diversity and a PIC value between 0.25 and 0.5 for a locus with intermediate diversity (David *et al.,* 1980).

Hardy-Weinberg Equilibrium (HWE): Hardy-Weinberg equilibrium explains that both gene and genotype frequencies will be constant from generation to subsequent next generations under the assumptions that no genetic drift, mutation, and natural selection happened in the population and the population is closed (no gene flow) and has a random mating pattern (Labate, 2000).

F-statistic (Fst): Fixation indices are the measures of standardized variances in allele frequencies that detect departure from HWE caused by biased inbreeding, out breeding, or population subdivision and genetic drift (Wright, 1950). Hence, the F statistic quantifies the mean heterozygosity difference between populations and subpopulations. Fst is considered to be the most informative statistic for examining the overall level of genetic divergence among subpopulations and can be calculated as:

$$Fst = \frac{(HT - HS)}{HT}$$

Where Fst is reduction in heterozygosity, H_T is average heterozygosity in a population and H_S average heterozygosity in a subpopulation.

The Fst value ranges between zero and one. When it is equal to zero, it means complete sharing of genetic material and when it is one, no sharing (the populations are fixed).

Analysis of Molecular Variance (AMOVA): is a method of estimating variance components within and among populations directly from molecular data and testing hypotheses about differentiation

(Excoffier *et al.*, 1992). AMOVA treats molecular data as a vector q_i which is a matrix of 1s and 0s, 1 indicating the presence of a marker and 0 its absence.

Euclidean distance: is one of the genetic distance measures based on allele frequency distribution between pairs of vectors calculated by subtracting the vector of one haplotype from another, according to the formula ($\mathbf{q}_j - \mathbf{q}_k$). If $\mathbf{q}_j$ and $\mathbf{q}_k$ are visualized as points in *n*-dimensional space indicated by the intersections of the values in each vector, with *n* being equal to the length of the vector, then the Euclidean distance is simply equal to the shortest distance between those two points. The distance between points p and q is the length of the line segment connecting them ($\overline{pq}$) (Aremu, 2012).

2.7.1 Multivariate statistics to estimate genetic diversity

Genetic diversity among different varieties and/or species can be assessed using multivariate statistics. This provides reliable information on the real genetic distances between genotypes hence it is a tool for assessment of genetic diversity (Bhanu, 2017). Some of the multivariate techniques include:

I. Cluster analysis

These techniques depict a pattern of similarity/relatedness between genotypes based on their evolutionary relationships and group the similar ones in the same group while differentiating the others. This method is mainly based on the unweighted paired group method using arithmetic mean (UPGMA) to provide precise grouping information on breeding materials used in accordance with pedigrees and calculated results found in agreement with known heterotic groups than the other clusters (Aremu *et al.,* 2007).

II. Principal component analysis (PCA)

Principal component analysis (PCA) can be described as a quantitative type of data reduction technique. This technique transforms multi-correlated variables into different sets of uncorrelated variables for further study (Bhanu, 2017). The new variables are in linear combinations with the original variables. It is based on the development of characteristic values and mutually independent principal components arranged in a decreasing order of variance. The technique is most suitable when different variables have the same unit and is difficult for different scales. This difficulty is avoided by standardizing all the variables and to do this each variable is divided by its estimated standard deviation. This technique is a means for further analysis, not an end (Bhanu, 2017).

2.8   Some statistical tools for genetic diversity analysis

I.   Numerical Taxonomy System for personal computer (NTSYSpc)

NTSYSpc is used to analyze genetic diversity from different molecular marker data and works based on similarity indices as a 0, 1 matrix of genotypic data. It is used for cluster analysis, principal component, and/or principal coordinate analysis (Rohlf, 1998).

II.   Genetic Analysis in Excel (GenAlEx)

GenALEx is an Excel add-in easy and user-friendly program designed for use with SSR, SNP, and AFLP, allozyme, multi locus markers and sequencing DNA data in genetic diversity analysis. It works with three data type's codominant data, dominant, and geographic data. Analyses performed include: observed and expected heterozygosity, marker index, fixation index, allelic patterns, haploid diversity by population, haploid diversity by locus, haploid disequilibrium and, Nei's genetic distance, principal component analysis and Shannon index (Bhanu, 2017).

III.   Popgene

Popgene software is a user-friendly package developed for the analysis of genetic diversity among and within natural populations. Codominant data, dominant and quantitative trait data are the data types it works on and performs population genetic structure analysis using markers or phenotype/trait data based on gene frequency, number of allele, polymorphic loci, gene diversity, Shannon index, homozygosity, gene flow, genetic distance (based on Nei coefficient) and produces a dendrogram based on UPGMA and neighbor-joining methods (Bhanu, 2017).

IV.   R statistical software

R is a free, open source, user friendly software based on a programming language developed in 1995 at the University of Auckland as an environment for statistical computing and graphics (Ikaha and Gentleman, 1996). Currently, several scientific disciplines, including medicine, agriculture, soil science, and ecology preferentially use R software due to its graphical capabilities and its free availability with different packages that are designed for analyzing different data types.

The free software R (https://www.r-project.org/) is a standard and preferable for the analysis of genetic data, offering packages that are dedicated to population genetics (Paradis, 2010), phylogenetics (Schliep, 2011) or genome-wide association studies (Clayton and Leung, 2007). When the R software is known as a standard for genetic data analysis, classical population genetics tools are being challenged by the increasing availability of genomic sequences since dedicated tools are needed for harnessing the large amount of information generated by currently available sequencing technologies.

The R package Adegenet for multivariate analysis: this R package is contributed and used to implement classes and functions to facilitate the multivariate analysis using genetic markers. The package allowed the use of big marker data and compresses and defines new formal classes of

genotypes (genind) or groups of genotypes (genpop), which can be used as an input to multivariate analysis. A lot of functions are also implemented to manipulate and analyze these objects, including recent developments in spatial genetics and data simulations. By assuring a good interoperability of data, adegenet contributes to making the R software a unifying platform for the analysis of genetic markers (Jombart *et al.,* 2008).

The R package Poppr for population genetic analysis: the R package Poppr gives significant, accessible tools for the analysis of clonal, partially clonal, and sexual populations available in one environment on all major operating systems. The capacity to analyze data for multiple populations across a user-defined hierarchy and provide novel functionality in R, combined with R's graphing abilities of publication-ready figures is thus obtained conveniently (Kamvar *et al.,* 2014).

The R package Ape for Phylogenetics and Evolution Analysis: Analysis of Phylogenetics and Evolution (APE) is a package written in the R language for use in molecular evolution and phylogenetics. APE enables the manipulation of phylogenetic trees, as well as several advanced methods for phylogenetic and evolutionary analysis such as comparative and population genetic methods (Paradis *et al.,* 2004, 2019).

The R package synbreed: the package synbreed was developed within the synbreed project for synergistic plant and animal breeding (www.synbreed.tum.de) and genetic data analysis. This package executes data processing, data analysis, and visualization since it contains a collection of functions that are embedded within the framework of a single, unified dataset that is required for genomic analysis (Wimmer *et al.,* 2012). Moreover, its implementation is flexible with respect to different ranges of data formats.

Pegas R package for AMOVA analysis: the package Pegas provides functions for data reading, writing, plotting, analyzing and manipulating allelic and haplotypic data. It is used for analysis of linkage disequilibrium (LD), population structure (fixation index (Fst)), analysis of molecular variance (AMOVA) and Hardy-Weinberg Equilibrium (HWE) (Knaus and Winter, 2020).

3 Materials and Methods

3.1 Plant material

A total of 363 Napier grass accessions that comprises 60 accessions from the ILRI genebank collection; 45 (25 Centro Nacional de Pesquisa de Gado de Leite (CNPGL), EMBRAPA's elite lines and 20 Brazilian Active Germplasm Bank of Napier Grass (BAGCE)) accessions from the Brazilian Agricultural Research Corporation (EMBRAPA), Brazil, 22 accessions from the United States Department of Agriculture (USDA), Tift, Georgia, USA, 31 accessions from the ICRISAT genebank, Patancheru, India (Supplementary Table S1) and a total of 205 progeny plants raised from seeds of 13 ILRI accessions (Table 1), were included in this genetic diversity study.

Napier grass seeds collected from 13 seed-bearing accessions and maintained in the ILRI forage genebank, approximately 20 to 30 seeds per accession were obtained and pre-germinated on agar medium containing potassium nitrate. The germinated seeds were transplanted into soil-filled pots and maintained in the screen house until they produce 3 to 4 leaves for sample collection. On average, about 16 progeny plants from each of the 13 accessions were sampled to determine the level of genetic diversity within and among genotypes. On the other hand, the recently introduced accessions from USDA and ICRISAT were propagated through stem cuttings. As indicated by Mannetje (1992), Napier grass stems were chopped into fragments consisting of at least 3 nodes in which two of the nodes were buried in the soil at a 45^0 angle during planting and were watered two times a day.

Table 1: Napier grass progeny plants raised from the 13 accessions. The detail of each progeny and accessions used in the study is shown in Supplementary Table S1.

3.2 DNA extraction and genotyping

Young leaf samples were collected from each individual plant into 2ml Eppendorf tubes, using ice in an ice-box and transferred to a -80 freezer as quickly as possible. The leaf samples freeze-dried for about 48 hours and ground into fine powder using a tissue grinder (tissue lyser). Genomic DNA was extracted from the leaf powder using a DNeasy® Plant Mini Kit (250) (Qiagen Inc.,Valencia, CA) following the manufacturer's procedures. The genomic DNA concentration and quality was checked using a Nano-drop spectrometer (DeNovix DS-11 FX spectrophotometer) and by using a 0.8% agarose gel electrophoresis. The concentration of the DNA was adjusted to 50 to 100 ng/µl and sent for DArTseq sequence genotyping under Integrated Genotyping Service and Support (IGSS) platform at BecA-ILRI, Nairobi, Kenya and genotyped as described in Muktar *et al*. (2019).

3.3 Data analysis

The genotype data was analyzed using different statistical tools; the missing percentage of data, expected heterozygosity, and polymorphic information content of the markers were calculated in Excel (Microsoft Excel for Office 365). The distributions of these markers were also analyzed and visualized using the R package synbreed (version 0.12-12) (Wimmer *et al.,* 2012). From the genome wide SNP markers, a subset of robust markers was selected based on their expected heterozygosity (He), polymorphic information content (PIC), missing value percentage, minor allele frequency (MAF), and genome wide distribution. The markers were further filtered based on their best contribution to the genetic differentiation and diversity by employing discriminant analysis of principal components (DAPC) (Jombart and Ahmed, 2011). The selected robust markers were used for genetic diversity and population structure analysis by using Euclidean genetic distance and neighbor-joining (NJ), Unweighted paired group method using arithmetic mean (UPGMA). Hierarchal clustering were calculated using the R functions *dist ()* and *NJ ()* and dendrogram or phylogenetic trees were generated using the Adegenet (Jombart *et al.,* 2008) and Poppr (Kamvar *et al.,*2014*)* packages in R statistical software. The degree of genetic similarity between genotypes was analyzed using Nei's genetic distance (Nei, 1972; Pagnotta, 2018). Genetic diversity and population stratification were analyzed by the Bayesian algorithm implemented in the STRUCTURE software (Corander *et al*., 2013; Pritchard, 2009) and DAPC (Jombart and Ahmed, 2011), using the filtered robust SNP markers. In addition, major clusters and sub clusters were detected using hierarchical clustering with complete linkage analysis (Kamvar *et al.,* 2014; Mohammadi and Prasanna, 2003) and Bayesian model based Population

Structure analysis was carried out using STRUCTURE software and the true value of K was determined using the method of Evano *et al. (*2005). AMOVA (Excoffier *et al.,* 1992) and fixation index (Meirmans and Hedrick, 2011) were employed to determine the extent of population differentiation among different groups and sub groups that were obtained from population structure analyses using the R package Pegas (Knaus and Winter, 2020). Diversity among and within accessions and progeny plants was analyzed using statistics on R software.

4   Results

4.1   Genome-wide distribution and polymorphism of the DArTseq markers

A total of 363 Napier grass genotypes from different collections and progeny plants were genotyped using the DArTseq platform and 96,454 SilicoDArT and 96,321 SNP markers were generated. Prior to further diversity analysis, genotype missing percentage was checked and 16 genotypes (6 progenies, 2 EMBRAPA collections, 1 EMBRAPA elite line, 3 ICRISAT, 3 USDA and 1 ILRI accession), which had high missing value ($\geq$ 50%) were excluded from further analysis hence a total of 347 Napier grass genotypes were used for diversity analysis.

The percentages of missing values of the markers ranged from 0.0 to 29.0 % for SilicoDArT markers and 0 to 83.7 % for SNP markers. The expected heterozygosity (He) and polymorphic information content (PIC) of the markers ranged from 0 to 0.5 and 0 to 0.38 respectively for both SilicoDArT and SNP markers while the average He was 0.26 and 0.18, and the average PIC was 0.21 and 0.15 for the SilicoDArT and SNP markers, respectively (Fig. 1).
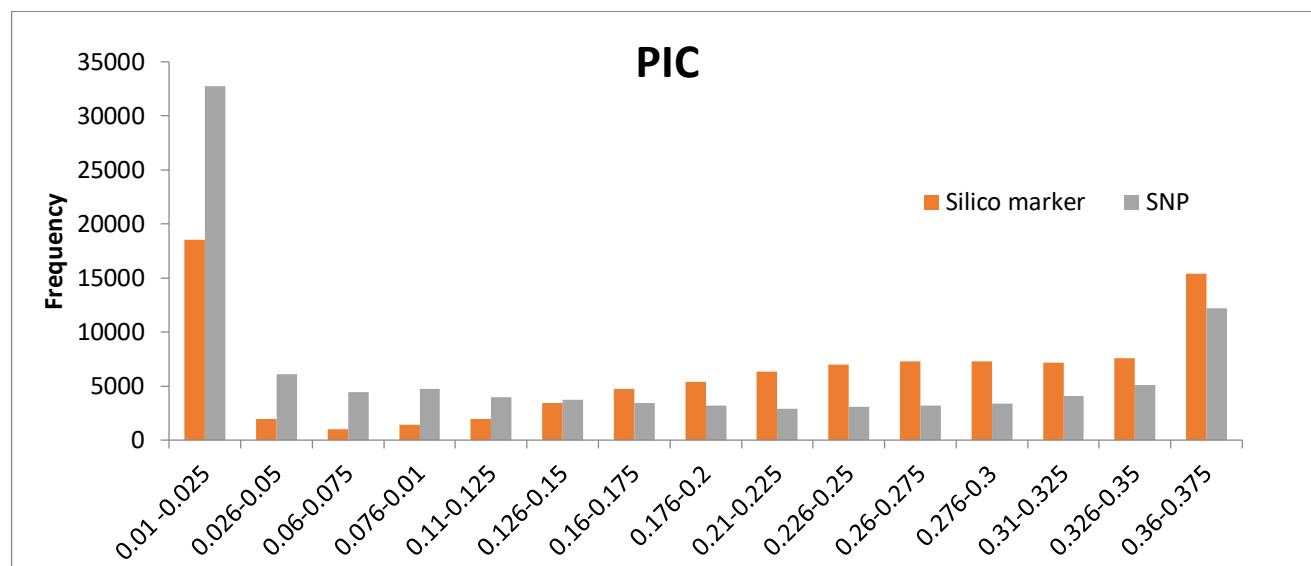

In line with the distribution of SilicoDArT markers throughout the genome of Napier grass, out of 96,453 markers, 76.28 % (73,573) mapped on to the fourteen linkage groups of the Napier grass genome (Yan *et al.,* 2020), while 1.73 % (1,669) mapped onto scaffolds and 21.99% (21,211) were found to be unmapped (unknown location). The highest number of markers were mapped to linkage group two (LG2) (7.32% (7,061) and (LG3) 7.14% (6,889) followed by LG1, LG7 and LG6, in which 6.87% (6,623), 6.61% (6,375) and 6.50% (6,267) were mapped respectively, while LG14 contained the least number of markers (3.36% (3,242)) (Fig. 2a).

From the 96,400 SNP makers, 88.82% (85,619) were aligned on to the fourteen linkage groups while 1.87% (1,802) mapped on to different scaffolds and 9.31% (8,979) were not able to be mapped on to the draft genome. Out of the aligned 88.82% markers, 8.74% were mapped on LG2 and 8.51% on LG3. The percentage of mapping for LG1, LG7, LG6, LG4 and LG13 were 7.69% (7,416), 7.40% (7,129), 7.32% (7,058), 6.50% (6,264) and 6.15% (5,925), respectively. The lowest numbers of markers 3.79% (3,655) were mapped on LG14 (Fig.2b).

Figure 2: The Distribution of SilicoDArT (a) and SNP (b) markers across the fourteen linkage groups (LG) of the Napier grass (*C. purpureus*) draft genome.

4.1.1 Marker selection for diversity study

From the 96,321 SNP markers generated, a subset of robust markers was selected based on the following criteria:

I. Markers with missing data percentage less than or equal to ten percent (NA% ≤ 10 %)

II. Minor allele frequency greater than or equal to five percent (MAF ≥ 5 %)

III. Polymorphic information content (PIC) greater than or equal to zero point two (PIC ≥ 0.2)

IV. Expected heterozygosity greater than or equal to zero point two (He ≥ 0.2)

V. Distribution of the markers across the linkage groups (LG) (genome-wide distribution)

VI. Markers contribution to diversity using the loading function in discriminant analysis of principal components (DAPC).

Stepwise marker selection was conducted in such a way that each criterion is taken into account after the previous criteria are considered. Hence, initially markers were selected based on missing value percentage (NA %) in which markers with missing value percentage of less than or equal to ten were retained while the rest were removed so that 79,831SNP markers were retained. Based on the second criterion of minor allele frequency (MAF ≥ 5 %), 3,629 SNP makers were retained. Further the third and fourth criteria of PIC and He reduced the markers to 2,357 SNP markers. Finally, 1001 robust and genome-wide distributed markers were selected based on the markers contribution to genetic diversity

and genetic differentiation according to the DAPC analysis by using the R package Adegenet. These selected 1001 SNP markers, with an average PIC value of 0.31, were used in genetic diversity and population structure analysis. The distribution of the selected markers was visualized using the R package synbreed and out of these selected markers, 1.8% (18) were unmapped, 0.9% (9) mapped to scaffolds, and the rest were distributed across the linkage groups with the highest distribution (map) number on LG2, (9.2% or 92 markers) and lowest number on LG14, which was 4.6% or 46 markers (Fig. 3).
Figure 3: Genome wide distribution of 1001 SNP markers selected based on different criteria, including the Discriminant Analysis of Principal Components (DAPC).

4.1.2 Genetic diversity in Napier grass populations

Genetic diversity and population stratification were detected by using DAPC, Structure software, and hierarchal clustering approaches and a significant amount of genetic diversity and population stratifications in the Napier grass collections and progeny plants with a high degree of consistency were obtained. The degree of genetic similarity between genotypes was identified using Nei's genetic distance (Nei, 1972) (Table 6). Furthermore, a high amount of genetic diversity and the extent of variation among clusters and sub clusters were confirmed by AMOVA (Table 7), and the fixation index (Fst) (Table 6).

4.1.3 Genetic diversity revealed by the Bayesian algorithm in STRUCTURE software

Population structure analysis using the Bayesian algorithm in structure software revealed two major clusters with ten sub clusters as suggested by the delta k (Dent, 2012) (Fig. 4a). Cluster I comprises almost half of the progeny plants (91 out of 199) and most of the EMBRAPA collection (BAGCEs, 15 out of 19), some accessions from the ICRISAT collection (9 out of 25), some from the ILRI collection (20 out of 59), two of the EMBRAPA elite lines (CNPGLs), and just one from the USDA collection. Cluster II is composed mainly of genotypes from the ILRI collection, progeny plants, most of the EMBRAPA elite lines (CNPGLs) and the USDA collection.

The collections were further grouped into ten sub-clusters, in which cluster I was further divided into six sub-clusters, while cluster II was divided into four sub-clusters (Supplementary Table S2). Eighty-one individual genotypes were found to be admixed (membership probability < 50 %) among the sub-clusters (Supplementary Table S3). The first sub-cluster from the population structure analysis consisted of 47 progeny plants (13 of the ILRI_NS_11, 16 of the ILRI_NS_7 and ILRI_NS_9, 14 of the ILRI_NS_3 and ILRI_NS_6, 3 of the ILRI_NS_13 and 1 of the ILRI_NS_4). The second sub cluster consisted of 6 genotypes that were entirely ILRI accessions. The third sub cluster consisted of 7 genotypes, all progeny plants from ILRI_NS_6. The fourth sub-cluster consisted of 23 genotypes (11 of the ILRI collection, 9 genotypes of the ICRISAT collection and 3 genotypes of the EMBRAPA collection). The fifth sub-cluster consists of 18 genotypes, out of these 12 were from the EMBRAPA collection, 3 were from the ILRI collection, 2 were EMBRAPA elite lines and one USDA genotype. The sixth sub-cluster consisted of 37 genotypes, all of which were progeny plants (10 of ILRI_NS_12 and ILRI_NS_13, 6 of ILRI_NS_10, 7 of ILRI_NS_7, 4 of ILRI_NS_4 and 2 of ILRI_NS_6). The

seventh sub-cluster consisted of 29 genotypes, of which 21 (72.41%) were from the ILRI collection, 4 (23.79%) were EMBRAPA elite lines, two were from the USDA and one from each of the ICRISAT and EMBRAPA collections. The eighth sub-cluster consisted of 27 genotypes, mostly genotypes from the USDA collection and EMBRAPA elite lines. The ninth sub-cluster consisted of 7 genotypes, of which six were from the ILRI collection and one was a USDA genotype. The last sub-cluster (sub-cluster X) consists of 66 genotypes, mostly represented by progeny plants (ILRI_NS_1, ILRI_NS_2, ILRI_NS_3, and ILRI_NS_5 and ILRI_NS_8) with only two genotypes from the ILRI collection and one from the ICRISAT collection.

4.1.4 Genetic diversity revealed by the Discriminant Analysis of Principal Components (DAPC)

DAPC clustered the population into ten clusters (K groups) (Fig. 5). The first cluster (K1) consisted of a total of 52 progeny plants, of which 38 (73.1%) were from ILRI_NS_12, ILRI_NS_13 and ILRI_NS_7. Generally, cluster I represents progeny plants while the second cluster consisted of 52 genotypes, out of these 50 genotypes were progeny plants and the other two were USDA and ICRISAT accessions. The third cluster consisted of 33 genotypes and of these 32 were progenies and one ILRI accession. The fourth cluster consisted of 44 genotypes and of these 19 were progeny plants while the remaining were contributed by BAGCE (1), CNPGL (8), USDA (9), ICRISAT (4) and ILRI (3) collections. The fifth cluster consisted of 28 genotypes, most were ILRI and CNPGL genotypes (11 and 9, respectively). The remaining four were ICRISAT and USDA genotypes. The sixth cluster consisted of six genotypes which were entirely from ILRI. The seventh cluster consisted of 30 genotypes, while half (15) of these were ILRI genotypes, 11 were ICRISAT genotypes, 3 were BAGCE and 1 was a USDA genotype. The eighth cluster consisted of 48 genotypes, while 46 were progeny plants and the remaining 2 were ILRI accessions. The ninth cluster consisted of 34 genotypes

from BAGCE (13), ILRI (8), ICRISAT (5), USDA (4) and CNPGL (4). The last cluster (cluster 10) consisted of 20 genotypes of these 16 were ILRI accessions, 3 were EMBRAPA elite lines and 1 was from the EMBRAPA collection.
Figure 5: The ten clusters detected by the Discriminant Analysis of Principal Components (DAPC) of the 347 Napier grass genotypes. The axes represent the first two Discriminants. Each circle represents a cluster, and each dot (point) represents an individual.

4.1.5 Genetic diversity revealed by the hierarchal cluster analysis

Hierarchical clustering with complete linkage (hclust) analysis resulted into two major clusters and up to ten sub-clusters (Fig. 6; Table 3), which is highly similar to the STRUCTURE clustering except that the genotypes identified as admixed by STRUCTURE are distributed across the different sub-clusters in this case.

Under the hierarchal cluster analysis, sub-cluster I represented 51 genotypes of these 50 were progenies (9 progenies from each ILRI_NS7 and ILRI_NS9, 10 progenies from each ILRI_NS12 and ILRI_NS13, 4 progenies from each ILRI_NS_10 and ILRI_NS_11, 3 from ILRI_NS_4 and 1 ILRI_NS_6) and the rest were ILRI genotypes. The second sub-cluster consisted of 34 genotypes in which all of them are progeny plants (ILRI_NS_1, 10, 11, 12, 13, 3, 4, 6 and 7 with respective number of 1, 8, 2, 4, 4, 3, 6, 2, and 4). The third sub-cluster consisted of 27 of progenies from ILRI_NS_11, ILRI_NS_3, ILRI_NS_4, ILRI_NS_6 and ILRI_NS_7 in proportion of 8, 7, 2, 6 and 4 respectively. The fourth sub-cluster consisted of 25 genotypes and of these 17 were ILRI, 5 were ICRISAT and 3 BAGCE genotypes. The fifth sub-cluster consisted of 23 genotypes out of these 22 were progenies (6 ILRI_NS_3, 4 for each ILRI_NS_4 and ILRI_NS_6, 1 for each ILRI_NS_5, ILRI_NS_9 and ILRI_NS_10, 2 and 3 ILRI_NS_1 and ILRI_NS_11 respectively, and the last 1 was an ICRISAT genotype. The sixth sub-cluster consisted of 46 genotypes from BAGCE (13), ILRI (11), ICRISAT (13), USDA (6), CNPGL (2) and ILRI_NS_4 (1). This sub-cluster generally represents most of the Napier grass collections. The seventh sub-cluster consisted of 48 genotypes of these 46 were progeny plants (10 from ILRI_NS_1, 2 from each ILRI_NS_11 and ILRI_NS_12, 7 were ILRI_NS_2, 3 were ILRI_NS_3, 1 from each ILRI_NS_4, ILRI_NS_12, ILRI_NS_5, and 8 ILRI_NS_8). The remaining two were from the ILRI collection. The eighth sub-cluster consisted of 26 genotypes, of these 7 and 2 were from USDA and ICRISAT, respectively. The remaining 17 genotypes were progeny plants of ILRI_NS_5, ILRI_NS_6 and ILRI_NS_8. Sub-cluster nine consisted of 36 genotypes out of these 27 were ILRI, 6 were CNPGL, 1 was BAGCE and 2 were USDA genotypes. The last sub-cluster (sub-cluster ten) consisted of 31 genotypes most of these were from EMBRAPA (16 CNPGL and 1 BAGCE). The rest, four from each of the ILRI, ICRISAT and USDA collections and two from the progeny plants.

Clustering (complete linkage) based on the first 5 PCs

4.2 Population differentiation and divergence analysis

The Nei's genetic distance reflected the diversity among the Napier grass collections and progeny plants and among clusters and sub-clusters. Based on the overall dataset, the pairwise Nei's genetic distance ranged from 0.07071 for sub-clusters I and VI to 0.5118 for sub-clusters II and IX (Table 4). The six ILRI genotypes in sub-cluster II showed high similarity among themselves, with 0.005 to 0.02 range of Nei's genetic distance, probably representing potential duplicates. Analysis of molecular variance (AMOVA) was used to partition the existing genetic variation into different components. In the current study, analysis of one level of molecular variance was carried out using the R package Pegas and the number of subpopulations which were determined with STRUCTURE software were used for AMOVA analysis. Variance components obtained by AMOVA were highly significant ($P < 0.00$) among populations (Table 5).

Estimated Mean value of fixation index (Fst) per cluster ranged from 0.3398 in cluster VI that contain progeny plants to 0.7621 in cluster VII, which mainly contains the ILRI collection (Table 6). Divergence among populations was estimated based on allele-frequency or Net nucleotide distance and the largest divergence (0.3777) was between sub-cluster IV and VII (Table 7).

Table 4. The Nei's genetic distance among the ten sub-clusters of Napier grass collections and progeny plants

5 Discussion

5.1 Enhancement of diversity in ILRI Napier grass collection

Napier (Elephant) grass originated from the tropical region of sub-Saharan Africa and has been distributed as forage crop into most tropical and subtropical regions of the world (Clayton *et al.,* 2013). Characterization of genetic diversity in Napier grass is a prerequisite for wise and effective germplasm conservation and utilization as well as developing efficient breeding programs (Negawo *et al.,* 2018; Negawo *et al.*, 2017). The ILRI forage genebank collected and conserved a diverse set of genotypes that are very variable in genetic and phenotypic traits. However, the diversity and population size is very limiting in selecting different desirable traits for different agro-ecological conditions. Therefore, the strategies followed to increase diversity by developing progeny plants raised from seeds produced by open pollination. This will increase the chance of developing new genetic makeup through recombination and unique genotypes can be identified and incorporated into the existing collection (Nielsen *et al.,* 2014; Zhou *et al.*, 2018). Furthermore, it is crucial to assess genetic diversity in order to ensure that the most diverse populations are identified and selected to widen the genetic base of this grass.

Marker-assisted breeding in Napier grass is usually hindered due to low genetic information as this forage crop is under researched. Therefore, development and implementation of large-scale informative markers like SNPs, assist breeders in differentiating the Napier grass germplasm at a genome level (Muktar *et al.,* 2019; Zhou *et al.*, 2018). Today, different molecular markers have been utilized for genetic diversity analysis in Napier grass (Bhandari *et al.,* 2006; Muktar *et al.,* 2019; Van De Wouw *et al.,* 1999; Wanjala *et al.,* 2013; Zhou *et al.,* 2018). DArTseq marker technology is a rapid, low-cost, and efficient method for genotyping, providing a broad genome coverage, and as a result, has been increasingly used in different plant species for different purpose's (Baloch *et al.,* 2017; Mace *et al.*, 2008; Wenzl *et al.,* 2004), as well as in Napier grass (Muktar *et al.*, 2019). In this study, the genetic diversity in different Napier grass collections and progeny plants was estimated using the DArTseq SNP markers, and considerable genetic variation among populations as well as genotypes was identified. Furthermore, potential duplicates and divergent groups were detected.

5.2 Marker diversity and genome-wide distribution

In this study, 347 Napier grass genotypes and progeny plants were used to assess genetic diversity. Initially, 363 genotypes were incorporated in the study but, later 16 genotypes were excluded from

further investigation due to their high missing value percentages (≥ 50 %). The GBS method of the DArT-seq markers was utilized to investigate genetic variability and differentiation within and among the 347 Napier grass collection and progeny plants. A total of 96,454 SilicoDArT and 96,321 SNP markers were generated, of which 1001 highly informative SNPs were selected for the diversity study. Previously, since Napier grass reference genome sequence was not generated, the closely related pearl millet (*Cenchrus americanus*) genome was used to identify the genomic position and genome-wide distribution of the SilicoDArT and SNP markers (Muktar *et al.*, 2019). In this study, the markers were mapped onto the new reference genome sequence of Napier grass, in which most of the markers were able to be mapped with a higher precision.

Expected heterozygosity and PIC of the DArTseq generated markers ranged from 0 to 0.5 and 0 to 0.38 for both silicoDArT and SNP markers, with the average He =0.26 and 0.18 and PIC = 0.21 and 0.15, respectively. The results of the markers quality parameters were comparable with that of other species. The average PIC values of the generated SilicoDArT and SNP markers was similar with Lesquerella and related species (0.21) (Cruz *et al.,* 2013) and lower than that of values identified in DArT markers of sorghum (0.41) (Emma *et al.,* 2008) and wheat (0.44) (Mona *et al.,* 2006) also, similar with PIC value (0.212) of SSR markers that were originally developed for pearl millet and used to asses genetic diversity in Napier grass due to the cross-species transferability of microsatellite markers (Kandel *et al.*, 2016) and slightly greater than the previous report made on Napier grass using a similar marker platform (Muktar *et al.,* 2019).

According to Botstein *et al.* (1980), the PIC values can be classified into highly informative (PIC value > 0.5), moderately informative (PIC value $0.25 \leq 0.5$) and slightly informative (PIC value ≤ 0.25) for multi allelic markers, such as SSR. However, the PIC value of SNP markers is restricted to the extreme PIC values of 0.5 (when the two alleles have the same frequencies) due to the bi-allelic nature of the SNP markers. The advantage of SNP markers is their abundance in the genome and their distribution across the genome, which has been observed in the Napier grass draft genome of the markers used in this study. The obtained result was also consistent with the previous report by Muktar *et al.* (2019) while a slightly higher average in He and PIC values were obtained in the current study indicating high marker polymorphism and distribution that could be attributed to the sample size difference of the population in this study.

5.3 Genetic diversity among Napier grass

The revealed patterns of genetic diversity were interesting in which STRUCTURE software identified two major classes and ten sub-clusters of the assayed genotypes (Fig. 4a and 4b). Moreover, the result from hierarchal clustering in complete linkage was in accordance with result from structure analysis (Fig. 6). The DAPC analysis resulted in ten K groups (clusters) indicating also highly consistent results with STRUCTURE and Hierarchal clustering for genetic diversity analysis. In addition, AMOVA showed that the two major groups and the ten subgroups detected were significantly different from each other. The high level of diversity was observed and this high variation, and population stratification could be attributed to the outcrossing and self-incompatibility nature of Napier grass (Souza *et al.,* 2019). Variation in geographic origin of the accession might have also contributed to the high genetic diversity, since the accessions were collected from different parts of the world. Selection and breeding system were additional factors with the possibility of their contribution for the genetic variation. However, in Napier grass genetic contribution of genetic drift and gene flow on genetic variation is expected to be low since this grass is mostly propagated through stem cutting, and due to its low seed germination rate (Wanjala *et al.,* 2013; Xie *et al.,* 2009).

In this study, half of the progenies and most of the BAGCE accessions with some accessions from ICRISAT and ILRI were clustered under the main cluster one while most of ILRI collections, CNPGL (EMBRAPA elite lines), USDA collections and half of the progenies also clustered under the second main cluster. Most of the progenies clustered under sub-cluster I, III, VI, and X while most of the ILRI collections were clustered under sub-cluster II, IV, VII, and IX. The majority of the CNPGL and USDA collections were clustered under sub-cluster VIII while most of the BAGCE collections clustered under sub-cluster V. In some cases, progenies with the same maternal plants and clustered under more than one sub-cluster, implying they had different pollen sources. However, mostly the clustering of the genotypes did not seem to be based on the geographical origin which is also consistent with the findings by Negawo *et al.* (2018); Kandel *et al.* (2016); and Muktar *et al.* (2019); while it is in contrast with reports made by Harris *et al.* (2009) and Lowe *et al.* (2003).

5.3.1 Population differentiation and genetic divergence

According to Weising *et al.* (2005), the extent of genetic variation in a species and its distribution among and within populations is determined by the interactions of various factors, including the evolutionary history of the species, genetic drift, mating system, gene flow, mutation, and selection. In general, outcrossing species retain most of their variation within populations whereas selfing species

allocate more variation among populations. For DNA based markers, among population genetic differentiation is often estimated according to Nei's (1972) genetic distance. However, AMOVA is nowadays even more widely used for the partitioning of genetic variation among populations and sub-populations (Excoffier *et al*. 1992). In accordance with this, the one level AMOVA of the current study estimated the variance among the sub populations and high levels of genetic differentiation among the sub populations were revealed. Fixation index (Fst) is also another important parameter for differentiation of populations and subpopulations and measures the degree of differentiation among populations in terms of allele frequencies. The values of Fst can be grouped into four categories with respect to genetic differentiation; very high (Fst > 0.25), high (0.15 - 0.25), intermediate (0.05 - 0.15), and low (0.0 - 0.05) (De Vicente and Fulton, 2003). In this study, the estimate of population differentiation in Napier grass collections and progeny plants using fixation index (Fst) revealed a relatively high level of differentiation among the populations. Mean fixation index (Fst) per cluster of the current study ranged from 0.3398 in cluster VI, that contains entirely progeny plants, to 0.7621 in cluster VII that consisted of most of the ILRI accessions, some EMBRAPA elite lines and the USDA collections. More differentiation was observed among progeny plants and the accessions and this could be attributed to the outcrossing nature of Napier grass (Souza *et al*., 2019).

From allele-frequency or Net nucleotide distance, the highest divergent result (0.3777) was between populations of sub-cluster IV (which consisted mostly of ILRI accessions with a few ICRISAT and EMBRAPA's accessions) and VII (which consisted of two ILRI accessions and 46 progeny plants), indicating the divergence between the accessions and progenies and showing the potential of progeny plants, that were produced from open pollination, for enhancement of diversity of the ILRI Napier grass collection with potential for future utilization in breeding programs. Most of the introduced accessions clustered away from the ILRI collections (Table. 3) hence increase the genetic base for future use.

Six potential duplicate genotypes are also identified in the ILRI collection and the accessions showed high genetic similarity among themselves, with 0.005 to 0.02 range of Nei's genetic distance. Identification of duplicate or redundant genotypes is important especially for the genebank to reduce the cost of conservation.

6 Conclusions and Recommendations

6.1 Conclusions

In this study, a large number of SNP and SilicoDArT markers with high distribution throughout the genome and high polymorphism were generated using the GBS method of the DArTseq genotyping platform. The markers have valuable information for genome wide identification of genetic diversity in Napier grass. The DArTseq-SNP markers were employed for genetic diversity and population structure analysis in Napier grass collections from different institutes EMBRAPA, USDA, ICRISAT, and ILRI gene-bank and progenies raised from 13 ILRI accessions. The genetic diversity using the molecular markers identified high genetic variation and detected potential duplicates and unique genotypes to enhance Napier grass diversity in the ILRI collection. Therefore, this genetic diversity information is valuable for various purposes, including germplasm conservation, wise utilization, and implementation of effective breeding programs.

Moreover, Results from the diversity parameters showed that the presence of up to ten sub populations with considerable variation among the sub populations. Sub-population IV and subpopulation VII were also found as the most divergent and genotypes from these sub-populations could be used in a Napier grass heterotic breeding program as potential parental plants. In general, the results of this study indicate the suitability of the populations in the future molecular genetic studies in Napier grass.

6.2 Recommendations

Based on the findings obtained in this study, the following recommendations were forwarded.

- ➢ Napier grass breeding programs should focus on the divergent genotypes from progenies and accessions and also from distantly related populations of ILRI and USDA accessions. The unique genotypes from the progeny and other collections should be incorporated into the existing collection.
- ➢ The ILRI accession from sub-cluster II showed high similarity/low genetic diversity and hence, attention should be given to characterize these genotypes and to avoid redundant genotypes
- ➢ Characterization of more populations is also very important and an in-depth study should be made in the future including quantitative trait loci (QTL) mapping and genome wide association mapping.

Appendices

Appendix 1: (Supplementary Table S1) List of Napier grass genotypes that were used in the study. The 13 ILRI accessions that were used to raise progenies and the progenies raised from them indicated by the same highlighted color with respect to their progenies. The 16 genotypes that were excluded from further analysis are highlighted in yellow.

loading plot for 1001 SNP markers that were selected from DPAC analysis

Loading plot
Genotype composition plot (compoplot) that shows membership probabilities of individual genotypes from DPAC analysis
